Abstract

Melorheostosis, a rare mesenchymal dysplasia, is one of the sclerosing bone disorders. It is a developmental error, with a sclerotomal distribution, involving frequently one limb. It may be asymptomatic, but pain, stiffness with limitation of motion, leg-length discrepancy and limb deformity may occur. On plain radiographs, melorheostosis shows as cortical hyperostosis with thickening, resembling flowing candle wax. Soft tissue calcification and even ossification may rarely be seen. In some rare and complicated cases, corrective surgery may be required. Until very recently, the etiology of melorheostosis was unknown, but now, it has been established that melorheostosis is due to a loss-of-function mutation in LEMD3 gene (also called MAN1), which encodes an inner nuclear membrane protein.

Keywords

mesenchymal dysplasia, sclerosing bone, cortical hyperostosis, pain, stiffness, LEMD3 gene, MAN1 gene

Disease name/Definition

Melorheostosis is a rare mesodermal disease and one of the developmental diseases of bone density. It is included in the “sclerotic bone dysplasias” along with other sclerosing disorders such as cranio-metaphyseal and diaphyseal dysplasias as well as the osteoscleroses: osteopetrosis and its “variants” pyknody sostosis, osteopoikilosis, osteopathia striata and melorheostosis. Occasionally, patients may exhibit more than one sclerosing disorder, e.g. osteopoikilosis and melorheostosis, a condition referred to as “mixed sclerosing bone dystrophy”, which indicates a strong interrelation among the entities mentioned above.

History

Melorheostosis was first described in 1922 by Léri and Joanny as “hyperostose en coulée”, i.e. flowing hyperostosis resembling dripping candle wax.

Etiology/Distribution

Until very recently, the etiology of melorheostosis was unknown. Both melorheostosis, osteopoikilosis, and Buschke-Ollendorff syndrome have recently been described as due to a loss-of-function mutation in LEMD3 gene (1). LEMD3 (also known as MAN1) encodes an integral protein of the inner nuclear membrane. The developmental error is at the site of both intramembranous and endochondral bone formation, predominantly the former. Its distribution often suggests a sclerotomal abnormality involving one or more sclerotomes or areas of bone innervated by an individual spinal sensory nerve (2). There is a definite tendency for monomelic distribution, i.e. involvement of one limb, but a single bone or
multiple different bones may be affected. Melorheostosis also shows a linear track involvement along the diaphysis/metaphysis/epiphysis, at times crossing contiguous bones and joints.

**Clinical and laboratory findings**
Age at presentation varies widely and melorheostosis may be seen in children and adults. There is no sex predilection. The condition is often asymptomatic, but pain, stiffness and deformity may be present, with limitation of motion. The course of the disease is insidious, with a slow chronic progression of symptoms and periodic exacerbations. Soft tissue involvement is associated with more evident restricted motion and stiffness due to soft tissue contracture, fibrosis an even ossification (3,4). There may be an associated limb-length discrepancy, tendon and ligament shortening, or rarely a malformation of blood or lymph vessels, and/or soft tissue fibromatosis (5-7). Limb swelling and edema may be seen, as well as hyperpigmented skin patches (8) or linear sclerodermatous skin changes (9). Serum calcium, phosphorus and alkaline phosphatase are normal.

**Imaging**
Cortical hyperostosis is readily seen on plain radiographs, extending along the length of one side of the bone and resembling flowing candle wax (Figure 1). In the carpal and tarsal bones and in the epiphyses, the hyperostosis may be round or irregular. Involvement of the axial skeleton is rare. Soft tissue calcification or ossification may be seen. Scintigraphy reveals abnormal increased tracer uptake in the bone and soft tissue lesions. It may be instrumental in confirming the diagnosis in equivocal cases (10). Computed tomography (CT) will also reveal the lesions and the clear demarcation between normal and abnormal bone. Magnetic resonance imaging (MRI) shows the bone and soft tissue lesions as areas of low signal, on all sequences (11,12). CT and MRI are not needed for diagnosis in the vast majority of cases, especially in children.

**Differential diagnosis**
In most cases of melorheostosis, biopsy is not needed for diagnosis. If performed, it is not diagnostic. Proper diagnosis is almost always evident on plain radiographs. Parosteal osteosarcoma may be in the differential diagnosis in more localized forms, and myositis ossificans or calcified hematoma in cases associated with soft tissue calcification or ossification.

**Treatment**
This may include surgery for tendon lengthening and correction of deformities. In extremely rare cases, amputation is indicated in very painful limbs with contractures and ischemia (13). Most cases are benign and do not require operative intervention (14).
